latch the BQ2010's Empty output.

The circuit in Figure 1 improves the BQ2010's current-spike immunity in several ways and adds several useful features. First, a 3.3V, current-limited low-dropout voltage regulator, IC4, supplies power to IC1, the BQ2010. Second, an LTC1477 short-circuit-protected, high-side FET switch, IC5, limits battery-to-load current to a maximum of 2A. To prevent IC1's SB (single-cell voltage) monitor pin from sensing an invalid Empty state, current-compensation amplifier IC3B makes the voltage to the SB pin current-independent. The negative rail of IC3B connects to the active side of the ground-referenced current-sense resistor, R4. With no load current, op amp IC3B's output should rest at 0V, but few rail-to-rail op amps provide outputs that go to 0V. The solution is to bias the positive side of the op amp enough to set the output above \( V_{OL} \) and compensate by lowering the gas-gauge-voltage sense-resistor ratio.

Additional features include a short-circuited load shutoff to prevent IC5 from going into thermal-protection mode (Figure 2). Also, the entire circuit shuts off when the battery provides no current to the load or when the battery is discharged. A timer circuit consisting of IC7, IC8 and IC9 provides an additional shut-off option. You can set the turnoff delay from minutes to days by changing \( R_{33} \) and \( C_7 \) to reduce the clock frequency, or by selecting other taps on binary ripple counters IC8 and IC9. Pressing switch S2 or starting a recharging cycle turns the controller back on. The parallel-connected sections of Schottky diode D6 provide a current path for recharging the battery.

Although the resistor values shown in Figure 2 apply to a specific application, you can customize the circuit for a battery's chemistry, capacity, internal resistance, cell count, and timer and display options. You can calculate component values via a Microsoft Excel 2002 spreadsheet in the Web version of this Design Idea at www.edn.com. All of the circuit's low-profile, surface-mounted components fit on one side of a 1.8-sq-in., four-layer board. The switches and LED readout connect to the pc board's underside.
VERSATILE SWITCHED-CAPACITOR charge-pump voltage converters can provide a negative supply voltage from a positive-voltage source or double a positive source’s voltage. However, certain applications that consist entirely of ECL (emitter-coupled-logic) circuits provide only a negative-voltage supply—for example, −5.2V. Figure 1 shows how you can use a switched-capacitor converter to obtain a positive power-supply voltage suitable for powering ECL-to-TTL (transistor-to-transistor-logic)-level translators and other circuits.

Although connections to IC1 may appear to be reversed, the bilateral characteristics of IC1’s internal switches allow use of IC1’s output pin as its power input. Capacitor C1 acquires a charge when IC1’s internal switches connect the CAP+ pin to ground and CAP− to the negative-voltage power source via the output pin, OUT. During the next half-cycle, IC1 connects CAP− to ground and CAP+ to IN (normally used as the input), transferring C1’s positive charge to output capacitor C3 and the load. With FSEL connected to OUT, an internal oscillator sets the charge-discharge cycle’s frequency to approximately 1 MHz.

As Figure 2 shows, IC1’s switches present internal resistances that affect the output voltage’s magnitude, which is lower than the input voltage and subject to less-than-ideal regulation as output-load current increases. For optimum performance, use low-ESR capacitors for C1, and input and output bypass capacitors C2 and C3.

JFETs offer LC oscillators with few components

Herminio Martínez, Joan Domingo, Juan Gámiz, and Antoni Grau, Technical University of Catalonia, Barcelona, Spain

BY USING JFETs in unusual configurations, you can design simple, high-frequency LC oscillators with few passive components. The structure for implementing the amplifier stage comprises a JFET transistor that you configure as a common drain (Figure 1).

When the JFET transistor works in the saturation zone, the drain current, \( I_D \), is:

\[ I_D = \frac{I_{DSS}}{V_P} \times (V_{GS} - V_P)^2 = I_{DSS} \times \left(1 - \frac{V_{GS}}{V_P}\right)^2, \]

where \( I_{DSS} \) is the maximum saturation current and \( V_P \) is the pinch-off voltage. You can model the JFET in this saturation zone in the small-signal regime using an infinite input impedance and a current source that the gate-source voltage controls. The following equation determines the small-signal transconductance of the transistor:

\[ g_m = \frac{2I_{DSS}}{|V_P|/V_P} \times \left(1 - \frac{V_{GS}}{V_P}\right). \]
You can configure an amplifier stage, based on a JFET transistor, as a common drain.

![Figure 1](image)

You can develop a Hartley oscillator based on a JFET transistor.

![Figure 3](image)

Gate resistance $R_G$ provides the necessary connection from the gate to ground. Its typical value is in the low-megohm range to provide the needed high impedance of the amplifier structure. Resistance $R_S$ biases the transistor; the following equation determines resistance:

$$R_S = \frac{V_{GSQ}}{I_{DQ}}.$$

To complete the oscillator circuit, you add an LC-resonant tank to the amplifier stage (Figure 2); the result is a Colpitts oscillator. The connection from the gate to ground for dc exists because of the inductance of the LC-resonant tank, removing the gate resistance of the amplifier.

Analyzing the circuit using the Barkhausen criterion, the frequency of oscillation $f_0$ of the circuit is:

$$f_0 = \frac{1}{\sqrt{\frac{L_1}{C_1 + C_2}} \frac{C_3}{C_1 + C_2}}.$$

The necessary condition on the capacitors so that the circuit can oscillate is:

$$g_m R_S \geq \frac{C_1}{C_2},$$

or, equivalently, the voltage gain, $A_V$, of the amplifier stage, $V_{OUT}(t)/V_{IN}(t)$, is:

$$A_V \geq \frac{C_1}{C_1 + C_2},$$

which demonstrates that the voltage gain in always lower than one.

Similarly, you can develop a Hartley oscillator based on a JFET transistor (Figure 3). The simulation and experimental results for the Colpitts oscillator circuit uses a 2N3819, an n-channel device, for the JFET. The PSpice parameters for this transistor are $I_{DSS}$ of 12 mA and $V_P$ of $-3$V. Simulation shows the voltage gain of the amplifier circuit is 0.3064, and, with $C_1$, having a value of 50 nF and $C_2$, having a value of 114 nF, the circuit oscillates (Figure 4), which also shows the start-up process of the oscillator. The voltage gain also shows that the design meets the start-up conditions on the capacitors:

$$A_V = \frac{g_m R_S}{1 + g_m R_S} = 0.3064 \Rightarrow g_m \times R_S = 0.4417 > \frac{C_1}{C_2} = 50 \div 114 = 0.4386.$$

Note that transconductance of the transistor is equal to the value of the slope of the curve $i_D=f(V_{GS})$ at this operating point. Depending on this point, the actual value of the transconductance will be larger or smaller. Confirming this value, when oscillations start up, the curve $i_D=f(V_{GS})$ restricts the amplitude of the output signal due to the reduction of the transconductance when $V_{GS}$ decreases to values close to the pinch-off voltage; in this zone of the curve, its slope and, therefore, the transconductance is smaller. The intrinsic nonlinearity of the JFET transistor limits the gain of the amplifier stage, and no additional circuit stabilizing the amplitude of the output signal is necessary.
Unlike legacy PC motherboards, an ATX-style motherboard controls its power supply’s on/off state. If ac power fails, many ATX motherboards do not automatically restart when power returns, and that behavior is unacceptable for a server system that must provide near-continuous service. Although some PCs provide BIOS configuration selections for “wake-on-LAN” or “wake-on-modem” operation, these options depend on another computer to provide the wake-up call. A few ATX motherboard chip sets offer an “always-on” BIOS option, but chances are, the motherboard that’s available for your server system isn’t one of these.

The circuit design in Figure 1 offers a reliable method of recovery from a power interruption. Upon restoration of ac power, an ATX power supply delivers a standby voltage of 5V dc at a maximum of 10 mA via Pin 9 of its power connector (Figure 2). With standby power available, low-power CMOS timer TLC555 CP IC1, functions as an astable oscillator and delivers pulses at approximately 4-sec intervals to MOSFET-output optoisolator IC2. The output of IC2 connects in parallel with the PC’s front-panel power-on switch and in effect “pushes the power switch” every 4 sec.

In most astable-oscillator designs based on the generic 555 timer, timing capacitor C3 connects from pins 2 and 6 to ground. Upon initial application of power, IC1’s output goes low, activating IC2 and generating an immediate power-on signal. Depending on the motherboard’s design, an immediate start-up signal may cause the motherboard to lock up. Connecting C3 as shown eliminates the initial start-up pulse.

When the power supply switches on, primary 5V power becomes available at pins 4, 6, 19, and 20, driving diode D1 into conduction and biasing Pin 7 of IC1 to a level that stops oscillation. Although IC1’s output (Pin 3) can directly drive a motherboard’s power-on input, MOSFET-output optoisolator IC2 removes the need to trace the polarity of the power-on switch’s connections. In addition, IC2 eliminates any possibility of incompatible logic levels that some 3.3V motherboards impose.

You can assemble the start-up circuit on a small section of prototyping board and splice its connections into the power supply’s wiring harness and power-on pushbutton wiring. Variants of ATX connectors exist, so verify wiring before connecting the start-up circuit.
